We present an observation of four new bottom baryons in proton-antiproton collisions at $\sqrt{s} = 1.96$ TeV. Using 1.1 fb^{-1} of data collected by the CDF II detector at the Fermilab Tevatron, we observe four $\Lambda_b^0 \pi^\pm$ resonances in the fully reconstructed decay mode $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$, where $\Lambda_c^+ \rightarrow p K^- \pi^+$. The probability for the background processes to produce a similar or larger signal corresponds to a significance of greater than 5σ . We interpret these baryons as the $\Sigma_b^{(*)\pm}$ states and measure their masses.

Only one bottom baryon, the Λ_b^0 , which consists of the u , d , and b quarks, has previously been directly observed [1, 2]. Recently the CDF II detector at the Fermilab Tevatron has accumulated the world's largest sample of fully reconstructed Λ_b^0 baryons with 3180 ± 60 (stat.) $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ candidates. This is made possible by the large $b\bar{b}$ production cross-section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV and the ability of the CDF II experiment to select online fully hadronic decays of b -hadrons with a specialized trigger system. In this Letter, we present the first observation of four new $\Lambda_b^0 \pi^\pm$ resonances, where $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ and $\Lambda_c^+ \rightarrow pK^- \pi^+$, using 1.1 fb^{-1} of data collected between February 2002 and March 2006. The $\Lambda_b^0 \pi$ states are interpreted as the lowest-lying charged Σ_b baryons and will be labeled $\Sigma_b^{(*)}$. The symbol Σ_b refers to Σ_b^\pm , while Σ_b^* refers to $\Sigma_b^{*\pm}$. Unless otherwise noted, any reference to a specific charge state implies the charge conjugate state as well.

The $\Sigma_b^{(*)+}$ baryons contain one b and two u quarks, while the $\Sigma_b^{(*)-}$ baryons contain one b and two d quarks; these states are expected to exist but have not been observed. Baryons containing one bottom quark and two light quarks can be described by heavy quark effective theory (HQET) [3]. The HQET approach assumes a limit of infinite mass for the heavy quark and provides systematic $1/m_Q$ corrections to that limit in calculations of hadron properties, where m_Q is the mass of the heavy quark. In HQET a bottom baryon consists of a b quark acting as a static source of the color field surrounded by a diquark system comprising two light quarks. In the lowest-lying $\Sigma_b^{(*)}$ states, the light diquark system has strong isospin $I = 1$ and $J^P = 1^+$, which couples to the heavy quark spin and results in a doublet of baryons with $J^P = \frac{1}{2}^+$ (Σ_b) and $J^P = \frac{3}{2}^+$ (Σ_b^*). This doublet is degenerate for infinite bottom quark mass. As the b quark mass is finite, there is a hyperfine mass splitting between the $\frac{3}{2}^+$ and $\frac{1}{2}^+$ states. There is also an isospin mass splitting between the $\Sigma_b^{(*)-}$ and $\Sigma_b^{(*)+}$ states.

Single gluon exchanges between the heavy quark and the light diquark system determine the spectroscopic properties of baryons [4]. There exists a variety of predictions for the $\Sigma_b^{(*)}$ masses from non-relativistic and relativistic potential quark models [5], $1/N_c$ expansion [6], quark models in the HQET approximation [7], sum rules [8], and lattice quantum chromodynamics calculations [9]. On the basis of [5–9], we expect $m(\Sigma_b) - m(\Lambda_b^0) \sim 180 - 210 \text{ MeV}/c^2$, $m(\Sigma_b^*) - m(\Sigma_b) \sim 10 -$

$40 \text{ MeV}/c^2$, and $m(\Sigma_b^{(*)-}) - m(\Sigma_b^{(*)+}) \sim 5 - 7 \text{ MeV}/c^2$. The difference between the isospin mass splittings of the Σ_b^* and Σ_b multiplets is predicted to be $[m(\Sigma_b^{*+}) - m(\Sigma_b^{*-})] - [m(\Sigma_b^+) - m(\Sigma_b^-)] = 0.40 \pm 0.07 \text{ MeV}/c^2$ [10]. The natural width of $\Sigma_b^{(*)}$ baryons is expected to be dominated by the P-wave one pion transition $\Sigma_b^{(*)} \rightarrow \Lambda_b^0 \pi$, whose partial width depends on the available phase space and the pion coupling to a constituent quark. For the range of predicted $\Sigma_b^{(*)}$ masses, the natural widths $\Gamma(\Sigma_b^{(*)})$ calculated from an HQET prediction vary between 2 and 20 MeV/c^2 [11].

The CDF II detector is described in detail elsewhere [12]. Its components and capabilities most relevant to this analysis are the tracking system and the ability to select displaced tracks from heavy flavor decays. The tracking system lies within a uniform axial magnetic field of 1.4 T. The inner tracking volume, with radii between 2.5 and 28 cm from the beam line, is occupied by a system of double-sided silicon microstrip detectors [13]. An additional layer of single-sided silicon microstrip detectors is mounted directly on the beampipe at an average radius of 1.5 cm. The remainder of the tracking volume is occupied by a cylindrical drift chamber [14], with a radial extent of 40 to 137 cm.

A displaced track trigger is employed to select bottom and charmed hadrons [15]. This trigger requires a pair of tracks with opposite charge, identified in the transverse view [16]. The tracks must have impact parameters d_0 which fall within the range $0.12 \text{ mm} < |d_0| < 1.00 \text{ mm}$, where d_0 is defined as the distance of closest approach of the track to the primary vertex in the transverse plane [17]. Each track is required to have transverse momentum $p_T > 2.0 \text{ GeV}/c$. The scalar sum of the tracks' transverse momenta is required to exceed $5.5 \text{ GeV}/c$ and the azimuthal angle between the tracks is required to be within the range $2^\circ - 90^\circ$. In addition, the intersection point of the triggered tracks is required to have a transverse displacement of at least $200 \mu\text{m}$ with respect to the beam line.

In reconstructing the decays $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ and $\Lambda_c^+ \rightarrow pK^- \pi^+$, the proton from the Λ_c^+ decay and the π^- from the Λ_b^0 decay are most likely to satisfy the displaced track trigger requirements. Therefore, we require that both must have $p_T > 2 \text{ GeV}/c$, while the K^- and π^+ candidates have $p_T > 0.5 \text{ GeV}/c$ to ensure well-understood tracking efficiency. We also require $p_T(p) > p_T(\pi^+)$ to suppress Λ_c^+ combinatorial background. No particle identification is used in this analysis. All particle hypotheses consistent with the candidate decay structure are attempted. In a 3-D kinematic fit, the Λ_c^+ daughter tracks are constrained to originate from a single point. The Λ_c^+ candidate is then constrained to the known Λ_c^+ mass, and the Λ_c^+ momentum vector is extrapolated to intersect the π^- momentum vector to form the Λ_b^0 vertex. The probability of the 3-D Λ_b^0 kinematic vertex

fit must exceed 0.1%, and the Λ_c^+ and Λ_b^0 must have p_T greater than 4.5 and 6.0 GeV/c, respectively. To suppress prompt backgrounds from the primary interaction, we make the following decay time requirements: $ct(\Lambda_b^0) > 250 \mu\text{m}$ and its significance $ct(\Lambda_b^0)/\sigma_{ct} > 10$. We define $ct(\Lambda_b^0) \equiv L_{xy}(\Lambda_b^0)m_{\Lambda_b^0}c/p_T(\Lambda_b^0)$ as the Λ_b^0 proper time, with $L_{xy}(\Lambda_b^0)$ defined as the length of the projection, onto the two-track momentum vector, of the transverse plane vector from the primary vertex to the Λ_b^0 vertex. We use event-by-event primary vertex position measurements when computing this vertex displacement. To reduce combinatorial and partially reconstructed decays, we also require $|d_0(\Lambda_b^0)| < 80 \mu\text{m}$, where $d_0(\Lambda_b^0)$ is the impact parameter of the Λ_b^0 candidate. To suppress the contributions from $\bar{B}^0 \rightarrow D^+\pi^-$ decays, where $D^+ \rightarrow K^-\pi^+\pi^+$, we require $m(pK^-\pi^+)$ to be within 16 MeV/c² of the known Λ_c^+ mass [18], and $-70 \mu\text{m} < ct(\Lambda_c^+) < 200 \mu\text{m}$. We define $ct(\Lambda_c^+) \equiv L_{xy}(\Lambda_c^+)m_{\Lambda_c^+}c/p_T(\Lambda_c^+)$ as the Λ_c^+ proper time, with $L_{xy}(\Lambda_c^+)$ defined as the length of the projection, onto the three-track momentum vector, of the transverse plane vector from the Λ_b^0 vertex to the Λ_c^+ vertex.

The invariant mass distribution of $\Lambda_c^+\pi^-$ candidates is shown in Fig. 1 overlaid with a binned maximum likelihood fit, with a clear $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$ signal at the expected Λ_b^0 mass. The invariant mass distribution is described by several components: the $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$ signal, a combinatorial background, partially and fully reconstructed B mesons which pass the $\Lambda_c^+\pi^-$ selection criteria, partially reconstructed Λ_b^0 decays, and fully reconstructed Λ_b^0 decays other than $\Lambda_c^+\pi^-$ (e.g. $\Lambda_b^0 \rightarrow \Lambda_c^+K^-$). The combinatorial background is modeled with an exponentially decreasing function. All other components are represented in the fit by fixed shapes derived from Monte Carlo (MC) simulations [19, 20]. Within the Λ_b^0 baryon and B meson groups of shapes, the normalizations are constrained by Gaussian terms to branching ratios that are either measured (for B meson decays) or theoretical predictions (for Λ_b^0 decays). The branching ratios of many yet-unobserved Λ_b^0 decay modes are extrapolated from $\mathcal{B}(\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-)$ [21] and $\mathcal{B}(\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-)$ [22] using the ratios of branching ratios in analogous \bar{B}^0 decays [18]; factorization is assumed in two-body $b \rightarrow c$ decays of Λ_b^0 . In the fit, the Λ_b^0 components are normalized relative to the $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$ signal. To normalize the B meson components, we explicitly reconstruct a $\bar{B}^0 \rightarrow (K^-\pi^+\pi^+)\pi^-$ signal in the $\Lambda_c^+\pi^-$ sample by replacing the proton mass hypothesis with the pion mass hypothesis. The yield is $N_{\bar{B}^0} = 774 \pm 72$ (stat.) events. We scale this number by the ratio of all B decays into four tracks observed in the MC simulation to the subset which results in a $(K^-\pi^+\pi^+)\pi^-$ signature; this ratio is found to be 1.75 [18]. The fit to the invariant $\Lambda_c^+\pi^-$ mass distribution results in 3180 ± 60 (stat.) $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$ candidates.

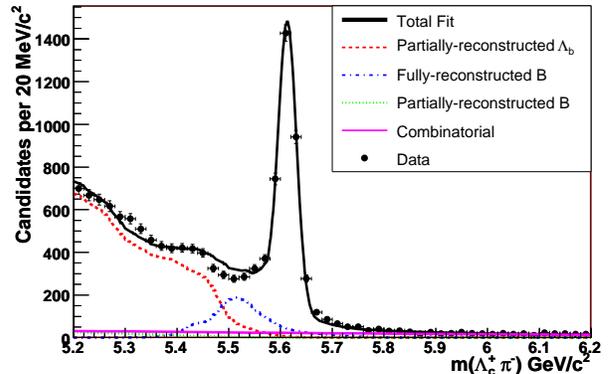

FIG. 1: Fit to the invariant mass of $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$ candidates. Fully reconstructed Λ_b^0 decays such as $\Lambda_b^0 \rightarrow \Lambda_c^+K^-$ and $\Lambda_b^0 \rightarrow \Lambda_c^+K^-$ are not indicated on the figure. The Λ_b^0 signal region, $5.565 \text{ GeV}/c^2 < m(\Lambda_c^+\pi^-) < 5.670 \text{ GeV}/c^2$, consists primarily of Λ_b^0 baryons, with some contamination from B mesons and combinatorial events. The discrepancies between the fit and data below the Λ_b^0 signal region are due to incomplete knowledge of the branching ratios of the decays in this region. We evaluate a systematic uncertainty for the effect of the model on the Λ_b^0 signal region sample composition.

The reconstruction of $\Sigma_b^{(*)}$ proceeds by combining Λ_b^0 candidates in the Λ_b^0 signal region with all remaining high quality tracks. A pion mass hypothesis is used when computing the invariant mass of the $\Sigma_b^{(*)}$ candidate. To minimize the contribution of the mass resolution of each Λ_b^0 candidate, we search for narrow resonances in the mass difference distribution of $Q = m(\Lambda_b^0\pi) - m(\Lambda_b^0) - m_\pi$. The $\Sigma_b^{(*)}$ candidates are divided into two subsamples using the charge of the pion from $\Sigma_b^{(*)}$ decay, denoted by π_{Σ_b} : in the $\Lambda_b^0\pi^-$ subsample the π_{Σ_b} has the same charge as the pion from Λ_b^0 while in the $\Lambda_b^0\pi^+$ subsample the π_{Σ_b} has the opposite charge as the pion from Λ_b^0 .

On the basis of the theoretical predictions in [5–9], the $\Sigma_b^{(*)}$ signal region is defined as $30 < Q < 100 \text{ MeV}/c^2$. We optimize the $\Sigma_b^{(*)}$ selection criteria using the pure background sample in the upper and lower sideband regions of $0 < Q < 30 \text{ MeV}/c^2$ and $100 < Q < 500 \text{ MeV}/c^2$. These sideband regions are parameterized by a smoothly varying function, a power law multiplied by an exponential. The signal is modeled by the PYTHIA [23] event generator where only the decays $\Sigma_b^{(*)} \rightarrow \Lambda_b^0\pi$, $\Lambda_b^0 \rightarrow \Lambda_c^+\pi^-$, and $\Lambda_c^+ \rightarrow pK^-\pi^+$ are allowed. For the optimization, we combine the $\Lambda_b^0\pi^-$ and $\Lambda_b^0\pi^+$ subsamples. We optimize cuts on the p_T of the $\Sigma_b^{(*)}$ candidate, the impact parameter significance $|d_0/\sigma_{d_0}|$ of the π_{Σ_b} track, and the $\cos\theta^*$ of the π_{Σ_b} track, where θ^* is defined as the angle between the momentum of the π_{Σ_b} in the $\Sigma_b^{(*)}$ rest frame and the direction of the total $\Sigma_b^{(*)}$ momentum in the lab frame. In this optimization, we

maximize $\epsilon(S_{\text{MC}})/\sqrt{B}$, where $\epsilon(S_{\text{MC}})$ is the efficiency of the $\Sigma_b^{(*)}$ signal measured in the MC simulation and B is the number of background events in the signal region estimated from the upper and lower sidebands. The maximum of $\epsilon(S_{\text{MC}})/\sqrt{B}$ is realized for $p_T(\Sigma_b) > 9.5$ GeV/ c , $|d_0/\sigma_{d_0}| < 3.0$, and $\cos\theta^* > -0.35$.

In the $\Sigma_b^{(*)}$ search, the dominant background is from the combination of prompt Λ_b^0 baryons with extra tracks produced in the hadronization of the b quark. The remaining backgrounds are from the combination of hadronization tracks with B mesons reconstructed as Λ_b^0 baryons, and from combinatorial background events. The underlying event tracks also contribute, but since they cannot be separated from the hadronization tracks, we use “hadronization” to denote the sum of the two contributions. The percentage of each background component in the Λ_b^0 signal region of $[5.565, 5.670]$ GeV/ c^2 is computed from the Λ_b^0 mass fit, and is made up of $(89.5 \pm 1.7)\%$ Λ_b^0 baryons, $(7.2 \pm 0.6)\%$ B mesons, and $(3.3 \pm 0.1)\%$ combinatorial events. Other backgrounds such as 5-track decays of B^+ mesons are negligible, as confirmed in inclusive single b -hadron simulations [19, 20]. The high mass region above the $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ signal in the Λ_b^0 mass distribution determines the combinatorial background. Reconstructing $\bar{B}^0 \rightarrow D^+ \pi^-$ data as $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ gives the B hadronization background. The Λ_b^0 hadronization background is obtained from a $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ PYTHIA simulation. The events in this simulation are reweighted so that the $p_T(\Lambda_b^0)$ distribution agrees with data. As the simulation has fewer low momentum tracks around the Λ_b^0 than found in data, the simulated events are further reweighted until the p_T spectrum of tracks around the Λ_b^0 is also consistent with data. After establishing the shape and normalization of each background Q distribution, the background shapes are parameterized by a power law multiplied by an exponential. The total background shape shown in Fig. 2 (inset) is compatible with the Q sidebands and is a fixed component in the $\Sigma_b^{(*)}$ fit.

In the Q signal region we observe an excess of events over the total background as shown in Fig. 2. The excess in the $\Lambda_b^0 \pi^-$ subsample is 118 candidates over 288 expected background candidates, whereas in the $\Lambda_b^0 \pi^+$ subsample the excess is 91 over 313 expected background candidates.

We perform a simultaneous unbinned maximum likelihood fit to the $\Lambda_b^0 \pi^-$ and $\Lambda_b^0 \pi^+$ subsamples for a signal from each expected $\Sigma_b^{(*)}$ state plus the background, referred to as the “four signal hypothesis.” Each signal consists of a Breit-Wigner distribution convoluted with two Gaussian distributions describing the detector resolution, with a dominant narrow core and a small broad component for the tails. The natural width of each Breit-Wigner distribution is computed from the central Q value [11]. The expected difference of the isospin mass split-

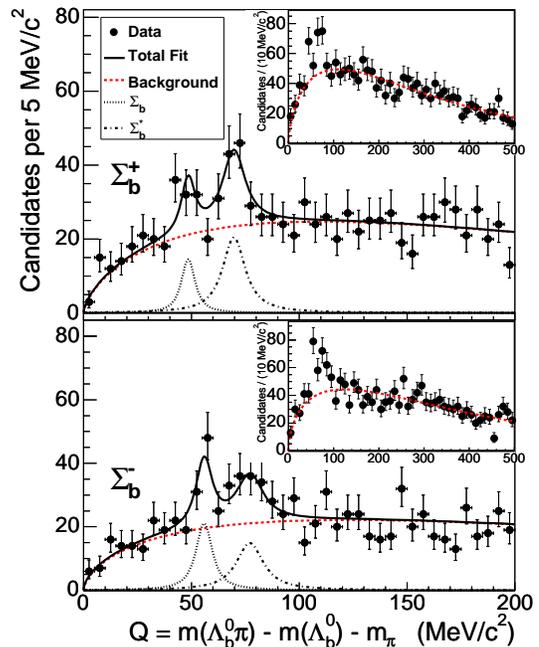

FIG. 2: The $\Sigma_b^{(*)}$ fit to the $\Lambda_b^0 \pi^+$ and $\Lambda_b^0 \pi^-$ subsamples. The top plot shows the $\Lambda_b^0 \pi^+$ subsample, which contains $\Sigma_b^{(*)+}$, while the bottom plot shows the $\Lambda_b^0 \pi^-$ subsample, which contains $\Sigma_b^{(*)-}$. The insets show the expected background plotted on the data for $Q \in [0, 500]$ MeV/ c^2 , while the signal fit is shown on a reduced range of $Q \in [0, 200]$ MeV/ c^2 .

tings within the Σ_b^* and Σ_b multiplets is below our sensitivity with this sample of data. Consequently, we constrain $m(\Sigma_b^{*+}) - m(\Sigma_b^+) = m(\Sigma_b^{*-}) - m(\Sigma_b^-) \equiv \Delta_{\Sigma_b^*}$. The four Σ_b signal fit to data, which has a fit probability of 76% in the range $Q \in [0, 200]$ MeV/ c^2 , is shown in Fig. 2.

Systematic uncertainties on the mass difference and yield measurements fall into three categories: mass scale, $\Sigma_b^{(*)}$ background model, and $\Sigma_b^{(*)}$ signal parameterization. The systematic uncertainty on the mass scale is determined by the discrepancies of the CDF II measured masses of the D^* , Σ_c , and Λ_c^* particles from the world average mass values [18]. The Q value dependence of this systematic uncertainty is modeled with a linear function, which is used to extrapolate the mass scale uncertainty for each $\Sigma_b^{(*)}$ Q value. This is the largest source of systematic error for the mass difference measurements, ranging from 0.1 to 0.3 MeV/ c^2 . The systematic effects related to assumptions made on the $\Sigma_b^{(*)}$ background model are: the sample composition of the Λ_b^0 signal region (*i.e.* amount of combinatorial background and contamination from B meson decays), the normalization and functional form of the Λ_b^0 hadronization background taken from a PYTHIA simulation, and our limited knowledge of the shape of the Λ_b^0 hadronization background (the largest source of systematic error on the yield measurements, ranging from 2 to 15 events). The systematic

effects related to assumptions made on the $\Sigma_b^{(*)}$ signal parameterization are: underestimation of the detector resolution by the simulation, the uncertainty in the natural width prediction from [11], and the constraint that $m(\Sigma_b^{*+}) - m(\Sigma_b^+) = m(\Sigma_b^{*-}) - m(\Sigma_b^-)$.

The significance of the signal is evaluated using the likelihood ratio, $LR \equiv L/L_{\text{alt}}$, where L is the likelihood of the four signal hypothesis and L_{alt} is the likelihood of an alternative hypothesis [24]. We study the alternate hypotheses of no signal, two Σ_b states (one per $\Lambda_b^0\pi$ charge combination), and three $\Sigma_b^{(*)}$ states, performed by eliminating one of the states in the four signal hypothesis. Systematic variations are included in the fit as nuisance parameters over which the likelihood is integrated. The resulting likelihood ratios are given in Tab. I. To assess the significance of the signal, we repeat the four signal hypothesis fit on samples randomly generated from alternate signal hypotheses. In 12 million background samples, none had a LR equivalent or greater than the one found in data. From these samples, we evaluate the probability for background only to produce four signals of this or greater significance to be less than 8.3×10^{-8} , corresponding to a significance of greater than 5.2σ . The probabilities for each of the alternate hypotheses to produce the observed signal structure is also given in Tab. I. The final results for the Σ_b measurement, including systematic uncertainties, are quoted in Tab. II. Using the CDF II measurement of $m_{\Lambda_b^0} = 5619.7 \pm 1.2$ (stat.) ± 1.2 (syst.) MeV/c² [2], we find the absolute masses of the Σ_b states given in Tab. II. The systematic uncertainties on the absolute Σ_b mass values are dominated by the total Λ_b^0 mass uncertainty.

Hypothesis	LR	p -value	Significance (σ)
No Signal	2.6×10^{18}	$< 8.3 \times 10^{-8}$	> 5.2
Two Σ_b States	4.4×10^6	9.2×10^{-5}	3.7
No Σ_b^- Signal	1.2×10^5	3.2×10^{-4}	3.4
No Σ_b^+ Signal	49	9.0×10^{-3}	2.4
No Σ_b^{*-} Signal	4.9×10^4	6.4×10^{-4}	3.2
No Σ_b^{*+} Signal	8.1×10^4	6.0×10^{-4}	3.2

TABLE I: Likelihood ratios (LR) in favor of the four $\Sigma_b^{(*)}$ state hypothesis over the various alternative hypotheses described in the text. Also shown is the probability for each hypothesis to produce the observed data (p -value), calculated using the LR as a test statistic on randomly generated samples.

In summary, using a sample of 3180 ± 60 (stat.) $\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-$ candidates reconstructed in 1.1 fb^{-1} of CDF II data, we search for resonant $\Lambda_b^0\pi$ states. We observe a signal of four states whose masses and widths are consistent with those expected for the lowest-lying charged $\Sigma_b^{(*)}$ baryons: Σ_b^+ , Σ_b^- , Σ_b^{*+} , and Σ_b^{*-} . This result represents the first observation of the $\Sigma_b^{(*)}$ baryons.

We thank T. Becher, A. Falk, D. Pirjol, J. Rosner,

State	Yield	Q (MeV/c ²)	Mass (MeV/c ²)
Σ_b^+	32^{+13+5}_{-12-3}	$48.5^{+2.0+0.2}_{-2.2-0.3}$	$5807.8^{+2.0}_{-2.2} \pm 1.7$
Σ_b^-	59^{+15+9}_{-14-4}	$55.9 \pm 1.0 \pm 0.2$	$5815.2 \pm 1.0 \pm 1.7$
Σ_b^{*+}	77^{+17+10}_{-16-6}	$\Delta\Sigma_b^* = 21.2^{+2.0+0.4}_{-1.9-0.3}$	$5829.0^{+1.6+1.7}_{-1.8-1.8}$
Σ_b^{*-}	69^{+18+16}_{-17-5}		$5836.4 \pm 2.0^{+1.8}_{-1.7}$

TABLE II: Final results for the Σ_b measurement. The first uncertainty is statistical and the second is systematic. The absolute Σ_b mass values are calculated using a CDF II measurement of the Λ_b^0 mass [2], which contributes to the systematic uncertainty.
